1 Introduction

The use of compliant joints in robotics has become popular in the last few decades for several different reasons. Springs in series with actuators has been widely studied and implemented, most notably through series elastic actuators [1]. This arrangement can allow for the more reliable implementation of force control, increase the adaptability of the mechanism to external contacts, and in the case of transmissions with low back-drivability, can allow a contact force to be applied at the output without power applied to the actuator. Compliance in parallel systems can be used to allow the underconstrained degrees of freedom in an underactuated mechanism to reconfigure in presence of an external contact [2,3].

We focus our attention on compliant joints used in parallel manipulators. Recently, several authors have studied how to model the stiffness matrix of parallel manipulators that use passive compliant joints and/or springs in series with the actuators [4–7]. In this kind of compliant manipulators, the forward kinematics have to be solved simultaneously with the static analysis [8], as each configuration will depend on the external applied force.

In this paper, we study the effect of passive compliant joints (such as flexure-based or spring-loaded joints) and springs in parallel with the actuators to reduce actuation force. Prior work has studied how to design parallel manipulators adding certain compliant elements that lead to a constant potential energy at any configuration, when no external force is applied (only gravity) [9–11]. In such gravity compensated manipulators, the actuation force is greatly reduced, resulting in significant improvement of the control and energy efficiency. However, there is not a general methodology to design such manipulators. Their challenging design process consists in expressing the potential energy as a function of a minimal set of coordinates. The condition for static balance is then obtained by imposing some coefficients depending on design parameters to be zero [9], but a feasible solution is not always possible and requires a complex ad hoc initial design. For instance, Ref. [9] shows a statically balanced six degrees of freedom manipulator using legs formed by compliant parallelogram mechanisms.

In this paper, we show how the springs in parallel with the actuated and passive joints can significantly reduce the force exerted by the motors in the presence of certain external forces without requiring such complex design process. Some of the big advantages of parallel manipulators over their serial counterparts are their high stiffness, accuracy and, their ability to support much higher loads. One of the major drawbacks is their small workspace, which are even more reduced when considering singularities [12] and the limits of the forces the motors can exert [13,14]. In this context, parallel platforms can greatly benefit from the use of springs in parallel with the actuators to help to reduce the required motor forces, enhancing the size of the usable workspace and reducing the size of the actuators.

Note that such manipulators will not be compliant. Indeed, the rigidity of the manipulator that uses compliance in the passive joints or compliance in parallel with the motors is not greatly modified, because the stiffness of the motors is usually several orders of magnitude bigger than the stiffness of the springs. Therefore, such passive compliance was usually ignored for the compliant analysis. However, in Ref. [15] they shown how taking the passive compliance into account can increase the accuracy of the model.

Our work is not focused on stiffness analysis of manipulators [4–7,16–19], but on the analysis of how compliance in parallel with the joints modifies the load on the motors. Other works have shown that springs can reduce the energy consumption by minimizing the sum of the actuation torques through motion trajectories for serial manipulators [20] or walking [21] and running robots [22]. We show that springs are also useful for reducing actuation torque for parallel mechanisms.

Our framework takes into account compliance in the passive joints and compliance in the actuated ones in parallel with the motors. We consider any joint with compliance as an active joint, for the purpose of computing the Jacobian matrix. In other words, our approach considers the parallel manipulator as redundant and uses screw theory to obtain the Jacobian matrix of the redundant manipulator that defines the transmission relationship between torques and external wrenches on the platform [23]. Using an appropriate definition of the torque for each type of joint, we can quantify the reduction or increase of torque that the motors have.
All the joints exerting torque are called active. Depending on the type of joint, the total force/torque they exert is

\[ \tau_i = \tau_i - k_i (\theta_i - \delta_i) \] for actuated compliant,

\[ \tau_i = -k_i (\theta_i - \delta_i) \] for passive compliant, and

\[ \tau_i = \tau_i \] for actuated joints,

where \( \tau_i \) is the torque/force exerted by the motor and \( k_i \) is the stiffness constant of the spring. Previous approaches have computed the influence of the passive compliant joints by adding an extra term in the static equations that depend on the Jacobian matrix relating the passive and the active joints [6]. Here, we propose to consider compliant parallel manipulators as redundant manipulators to compute its Jacobian matrix. In Sec. 2.2, we review the method of deriving the Jacobian matrix of parallel manipulators using screw theory.

2.2 The Jacobian Matrix of Redundant Parallel Manipulators

Consider a parallel manipulator in \( \mathbb{R}^3 \). Its platform can be moved in a maximum of 6 degrees of freedom (DOF), 3 for position, and 3 for orientations, defined in a vector \( x \in \mathbb{R}^6 \). Depending on the number of legs, links, and joints, we can compute the mobility of the manipulator, \( n \), using the Grüber–Kutzcher criterion. If \( n < 6 \), the manipulator is called lower mobility [25], that is, the workspace of the manipulator consists of a \( n \) dimensional subspace of the six-dimensional task space. If the mobility is higher than 6, the manipulator workspace is still six-dimensional, but it has kinematic redundancy [26].

For simplicity, we consider only 1 DOF joints. In other words, a universal (spherical) joint is considered as two (three) rotational joints with intersecting axes. We assume that the manipulator has full mobility (\( n = 6 \)). Then, if the manipulator has \( l \) equal legs, each leg has to have 6 joints to allow the full mobility of the platform. Therefore, the total number of joints is \( m = 6l \). Let

\[ \Theta = (\theta_{11}, \ldots, \theta_{60})^T \]

be the vector of all the joint angles. Only \( n \) of them are independent and determine the position of the platform. Let \( n_a \) be the number of joints actuated by a motor. If \( n_a = n \), the manipulator is called fully actuated. If \( n_a > n \), the manipulator is said to be redundantly actuated. Note that the number of actuated joints must be at least the same as the mobility, otherwise, the manipulator would have uncontrolled free DOFs.

The twist acting on the platform \( T = (v, \Omega) \), composed of linear velocity and angular velocity, can be written as linear combination of the twists defined by each of the joints of the legs [27,28]. Mathematically, that is

\[ T = \sum_{j=1}^{6} \theta_j S_j, \quad i = 1, \ldots, l \]

where \( S_j \) corresponds to the screw associated to the \( j \)th joint of the \( i \)th leg and \( \theta_j \) is the velocity of the \( j \)th joint on the \( i \)th leg. For a rotational joint located at \( p \) with an axis of rotation along \( z \), its associated screw is \( (z, p \times z) \). For a prismatic joint along \( z \), its associated screw is \( (0, z) \).

In each leg, let \( g \) of the joints be active (that is, either compliant or actuated), while the rest (\( 6 - g \)) are free to move. To eliminate the passive variables from Eq. (3), we compute the system of screws that are reciprocal to the passive joint screws. Two screws \( S_1 = (v_1, w_1) \) and \( S_2 = (v_2, w_2) \) are reciprocal when their reciprocal product is zero, that is,

\[ S_1 \ast S_2 = v_1 \cdot w_2 + w_1 \cdot v_2 = 0 \]

There are \( 6 - (6 - g) = g \) screws reciprocal to the passive joints [29,30]. Let \( S_{ik} \), for \( k = 1, \ldots, g \), be the system of screws reciprocal to the passive joint screws. If we apply the reciprocal product
at both sides of the equations in Eq. (3), we can rewrite the system as

$$J_f T = J_\theta \begin{pmatrix} \dot{\theta}_1 \\ \vdots \\ \dot{\theta}_h \end{pmatrix}$$

(5)

where

$$J_f = \begin{pmatrix} s_{11}^T \\ \vdots \\ s_{lg}^T \end{pmatrix}$$

(6)

and

$$J_\theta = \begin{pmatrix} s_{r1} * s_{11} & \ldots & s_{r1} * s_{lg} \\ \vdots & \ddots & \vdots \\ s_{rg} * s_{11} & \ldots & s_{rg} * s_{lg} \end{pmatrix}$$

(7)

Writing the \(l\) equations in a single matrix system form, we get

$$J_f T = J_\theta \begin{pmatrix} \dot{\theta}_1 \\ \vdots \\ \dot{\theta}_h \end{pmatrix}$$

(8)

where

$$J_T = \begin{pmatrix} J_f \\ \vdots \\ J_{lh} \end{pmatrix}$$

(9)

is a \(lg \times 6\) matrix and

$$J_\theta = \begin{pmatrix} J_{r1} & \ldots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \ldots & J_{rg} \end{pmatrix}$$

(10)

is \(lg \times lg\). Then, the Jacobian matrix of the parallel manipulator is usually defined as \(J = J_\theta^{-1} J_f\), and the relationship between the platform twist and the joint velocities as

$$JT = \dot{\Theta}$$

(11)

A wrench acting the platform is composed by a force and a moment \(W = (f, m)\). The above equation is used with the principle of virtual work to obtain the static equilibrium equations [27]. As a result, the relationship between the torques exerted by the joints and the transmitted wrench on the platform, is

$$W = J^T \tau$$

(12)

where \(J^T\) is the transposed of the matrix in Eq. (11), and it has dimensions \(6 \times lg\). The system is then in static equilibrium when the external applied wrenches \(W\) satisfies

$$W = -J^T \tau$$

(13)

3 Measuring the Influence of Compliance

3.1 Motor Force and Compliance. This work studies in detail how springs in parallel with the motors can affect the performance of the manipulator and the required motor output.

$$\tau_m = -(\tau_f + \tau_s)$$

Fig. 2 Simple example of the combination of actuation torque exerted by the motor \(\tau_m\), compliant torque exerted by the spring \(\tau_s\), and reaction torque to the external force \(\tau_f\)

In Fig. 2, we show two links connected by an actuated revolute joint with a torsional spring in parallel. If no external force is applied, the motor will need to overcome only the torque exerted by the spring. In other words, in a static equilibrium configuration, if \(\tau_i = -K(\phi_i - \phi_{0i})\) is the spring torque, where \(K\) is the stiffness constant and \(\phi_{0i}\) is resting configuration, the motor exerts a torque \(\tau_m = -\tau_s\) to maintain the link at angle \(\phi_i\). An external force \(f\) applied on the tip transmits a torque on the joint of magnitude \(\tau_f = (q - p) \times f\), such that the torque the motor needs to exert to achieve static equilibrium is \(\tau_m = -(\tau_s + \tau_f)\).

In this very simple case, it is obvious that the motor will reduce the exerted torque when the signs of the motor and spring torques are opposite, and there is always a configuration for which it can be reduced to 0.

For a parallel manipulator with several links and joints, we represent all the torques exerted by the springs in a vector \(\tau_s = (-K_i(\phi_i - \phi_{0i}))^T\), where \(K_i\) is the spring stiffness constant of the spring in the joint \(i\) and \(\phi_{0i}\) its resting configuration (linear or torsional depending on the type of joint). Similarly, we write the forces/torques exerted by the motors in a vector \(\tau_m = (\tau_f)^T\). The vector of forces/torques transmitted by an external wrench \(W = (f, m)^T\) is given by the relationship in Eq. (12). \(W = J^T \tau\).

The relationship between the vector of all the joint forces/torques is, analogously as the previous case, \(\tau_m = -(\tau_s + \tau_f)\). To avoid inverting the Jacobian matrix, we can multiply at both sides of the equality by \(J^T\), leading to

$$-W = J^T \tau_m + J^T \tau_s$$

(14)

This expression is equivalent to substituting the values of the torques given in Eq. (1) into the expression in Eq. (13). Note that, if the joint \(j\) is actuated without compliance, the corresponding \(j\) component in the vector \(\tau_s\) is zero. Similarly, if the joint \(j\) is passive compliant, the corresponding position \(j\) in the vector \(\tau_m\) is zero. We believe that this equation is simpler than the model introduced in Ref. [6], and they are equivalent.

Also, for a fully-actuated manipulator, the number of motors is 6 and thus, there are only 6 nonzero elements in the vector \(\tau_m\). Let \(\tau_m\) be the motor torques vector without the zero components. Then, we can rewrite the system as

$$-F = J_m^T \tau_m + J^T \tau_s$$

(15)

where \(J_m\) is a \(6 \times 6\) matrix obtained from \(J^T\) eliminating the columns corresponding to 0 torque. This system states a one-to-one correspondence between external applied wrench and motor forces/torques.

Given an external wrench, in each configuration we can solve the system for \(\tau_m\). Let us call a solution of the system \(\tau_m\) (C stands for compliance). Then, \(T_C\) gives us the torques exerted by the motors for a mechanism including springs. We call \(T_{NC}\) the solution of the same system with \(\tau_s\) set to zero. Then, \(\tau_{NC}\) are the torques done by the motor for a mechanism without compliant joints.
Thus, comparing the values $\tau_{NC}$ and $\tau_C$ we can quantify the decrease or increase of the torque done by the motors in a given configuration and for a given force.

Singular poses are defined by those configurations where $\det(J_{\text{ss}}) = 0$. Near such configurations, the values of the actuation torques can be very high even with small external applied forces. Therefore, in practice, the borders of the static workspace (or reachable workspace) are defined by those configurations that reach the limit on the torques that the motors can exert [13]. Thus, with Eq. (15) we have shown that adding springs in parallel with the joints can change those limits.

We will show how to design the spring parameters to maximize the number of configurations where the springs help to reduce the torque exerted by the motors, increasing then the efficiency of the manipulator. We will also show how we can quantify and visualize the configurations where the torque is reduced and for which range of forces.

### 3.2 Measuring Compliance Influence

In a configuration $P$, we define the overall force/torque exerted by the motors as the sum of the squares of all the force/torques exerted by the motors for both the mechanism with springs or without

$$\begin{align*}
\text{OT}_{CP} &= \tau_C^T \tau_C \\
\text{OT}_{NCP} &= \tau_{NC}^T \tau_{NC}
\end{align*}$$

The square of the torque is a positive magnitude proportional to the electrical power consumption of the motor. The total overall torque is obtained summing $\text{OT}_{CP}$ for all the configurations in the workspace

$$\text{TOT}_{CP} = \sum_{P \in WS} \text{OT}_{CP}, \quad \text{TOT}_{NCP} = \sum_{P \in WS} \text{OT}_{NCP} \tag{17}$$

To optimize the reduction of the overall torque for a given applied force, we first discretize the workspace of the manipulator. We set as parameters the stiffness constants of the springs and their resting positions $(k_j, \delta_j)$, for $j = 1, \ldots, m$. At each configuration, we solve the system in Eq. (15). As it is a linear system, the system can be solved analytically, and then used to compute $\text{OT}_{CP}$. In each configuration, $\text{OT}_{CP}$ is a polynomial expression of the parameters $(k_j, \delta_j)$ that is always positive. The sum of all the polynomials $\text{OT}_{CP}(k_j, \delta_j)$ for all the configurations of the workspace gives $\text{TOT}_{CP}(k_j, \delta_j)$, which is also an always positive polynomial and can be minimized.

If several forces are considered, for example a discretization of a cone of forces, we can repeat the computation of the sum of all the $\text{OT}_{CP}(k_j, \delta_j)$ in each configuration of the workspace for each of the forces in the cone. The minimization of the resulting sum gives the spring parameters that better reduce the overall actuation torque for the forces inside the cone.

We used Wolfram Mathematica 9 for the simulations running under Windows 64bit, 16GB RAM. As a preliminary computation, we need to compute the workspace, which requires solving the inverse kinematics for each tested configuration, and thus, depending on the architecture it can be simpler or more expensive. Given the workspace, deducing the expression of $\text{TOT}_{CP}(k_j, \delta_j)$ takes about 0.054 s per configuration. Therefore, the computation time depends on the discretization of the workspace. Once the expression of $\text{TOT}_{CP}(k_j, \delta_j)$ is obtained, we use the Mathematica NMinimize() procedure to obtain the minimum of the functions for a given set of constraints.

It is important to realize that, by definition, the springs cannot reduce the overall torque for all the possible applied forces. But in general, a parallel manipulator will be operating in a specific region of the workspace and subjected to a subset of all possible forces specified for the required task and gravity. As an example, a flight simulator will have to primarily overcome a vertical force in the direction of gravity.

We measure the increase or decrease of exerted motor forces in a configuration by computing the percentage

$$\frac{\text{OT}_{CP} - \text{OT}_{NCP}}{\text{OT}_{NCP}} \times 100\%$$

As a measure of the net improvement through all the workspace, we define the net percentage of increase/decrease as

$$\frac{\text{TOT}_{C} - \text{TOT}_{NC}}{\text{TOT}_{NC}} \times 100\%$$

The overall torque gives an idea of the electrical power consumption, but the limits of the workspace are usually limited by the maximum exerted motor force/torque. For this reason, we define an additional metric of motor force/torque as the maximum exerted in a configuration $P$ as

$$\text{MT}_{CP} = \max[\tau_C] \quad \text{MT}_{NCP} = \max[\tau_{NC}]$$

and the total maximum motor force/torque across the workspace as

$$\text{TMT}_{C} = \sum_{P \in WS} \text{MT}_{CP} \tag{21}$$

Then, similarly as before, the percentage of increase or decrease of maximum motor torque in a configuration is defined as

$$\frac{\text{MT}_{CP} - \text{MT}_{NCP}}{\text{MT}_{NCP}} \times 100\%$$

and the net increase as

$$\frac{\text{TMT}_{C} - \text{TMT}_{NC}}{\text{TMT}_{C}} \times 100\%$$

Note that the maximum torque is not a continuous function, and therefore, it cannot be minimized as done with the overall torque. Instead, we use the maximum motor torque as a measure to evaluate the results obtained minimizing the overall torque.

We use these performance measures in Secs. 4 and 5 to compute the optimal parameters for the springs of two examples of parallel manipulators.

### 4 Example Application I: The Stewart-Gough Platform

Consider the Stewart-Gough platform in Fig. 3-top. In Ref. [31] it was shown how this design is kinematically equivalent to the well-known octahedral design [32], having the same forward kinematic solution and the same singularities.

The base and platform attachments in their local reference are named $P_i$ and $Q_i$, respectively. The position and orientation of the platform are given by a position vector $p \in \mathbb{R}^3$ and a rotation matrix $R \in \text{SO}(3)$. Then, the coordinates of the attachments with respect to the fixed reference frame located at the center of the base are $p_i = P_i$ and

$$q_i = p + R Q_i \tag{24}$$

The proposed design has the attachments in the base and in the platform aligned in a way that we can write

$$p_{2i} = \lambda p_{2i-1} + (1 - \lambda) p_{2i+1} \quad \text{and} \quad q_{2i+1} = \lambda q_{2i} + (1 - \lambda) q_{2i+2} \tag{25}$$
compose the universal joint, with axes forming the platform spherical attachments (see Fig. 3 and of each leg are composed of three intersecting rotational axes).

Table 1 Joint axes coordinates for the Stewart-Gough platform

<table>
<thead>
<tr>
<th>Leg I</th>
<th>First axis</th>
<th>Second axis</th>
</tr>
</thead>
<tbody>
<tr>
<td>i = 1, 6</td>
<td>(z_i = (p_i - p_j)/\lambda)</td>
<td>(w_i = z_i^1)</td>
</tr>
<tr>
<td>i = 2, 3</td>
<td>(z_i = (p_i - p_j)/\lambda)</td>
<td>(w_i = z_i^1)</td>
</tr>
<tr>
<td>i = 4, 5</td>
<td>(z_i = (p_i - p_j)/\lambda)</td>
<td>(w_i = z_i^1)</td>
</tr>
</tbody>
</table>

for \(i = 1, 2, 3\) and indexes computed modulus 6, where \(\lambda\) represents the distance between the aligned attachments (see Fig. 3).

In each leg, the first and second joints are the two DOFs that compose the universal joint, with axes \(z_i\) and \(w_i\), and angles \(\theta_{1i}\) and \(\theta_{2i}\), respectively, and the third joint corresponds to the prismatic joint following the direction of the unit vector \(u_i = (q_i - p_i)/\lambda\) (Fig. 3-bottom). The forth, fifth, and sixth joints of each leg are composed of three intersecting rotational joints forming the platform spherical attachments (see Fig. 3 and Table 1 for detailed description of the axes).

4.1 Kinematic Analysis and Jacobian Matrix. The forward and inverse kinematics can be obtained solving the system

\[
(p_i - q_i)^2 = l_i^2, \quad \text{for} \quad i = 1, ..., 6
\]

where \(l_i\) are the lengths of the legs.

It is well known that the Jacobian matrix of the Stewart-Gough platform is formed by the line screws defined by the legs. However, in this example, we consider compliance in parallel to the actuated prismatic joints and also in the passive universal joints at the base. As a result, we need to compute the Jacobian matrix of the corresponding redundant manipulator.

For each leg, we choose screws reciprocal to the 4th, 5th, and 6th joints, and two additional joints. Then, for each leg \(i\), the set of reciprocal screws are

\[
\begin{align*}
\mathbf{s}_{i1} &= (\mathbf{u}_i \times \mathbf{w}_i, \mathbf{q}_i \times (\mathbf{u}_i \times \mathbf{w}_i)) \\
\mathbf{s}_{i2} &= (\mathbf{u}_i \times \mathbf{z}_i, \mathbf{q}_i \times (\mathbf{u}_i \times \mathbf{z}_i)) \\
\mathbf{s}_{i3} &= (\mathbf{u}_i, \mathbf{q}_i \times \mathbf{u}_i)
\end{align*}
\]

(27)

We can build the 6 matrices \(\mathbf{J}_i\) following the direction of the unit vector \(\mathbf{u}_i\) and the base side \(1\)m and platform side \(0.75\)m. The offsets of the base and platform attachments correspond to \(\lambda = 0.1\)m in Eq. (25).

We discretize the workspace in position and orientations as follows. Consider the vector \(\mathbf{A}\) orthogonal to the platform plane. We define the rotations of the platform as the cone of possible directions of the vector \(\mathbf{A}\) that spans two dimensions of possible rotations \((R_1\) and \(R_2\)), where the maximum angle between two possible \(\mathbf{A}\) vectors represents the opening angle of the cone [33]. The additional rotation around \(\mathbf{A}\) represents the 3rd dimension of rotations \((R_3\) Fig. 4). We consider a discretization of the 6-dim workspace of 13,247 configurations that include a range of directions of \(\mathbf{A}\) inside of a cone with opening angle of \(5\pi/6\) rad and \(R_2\) from \(-\pi/3\) to \(\pi/3\). The prismatic joint limits are \(l_i \in [0.5, 1]\), and the universal joint limits are \(\theta_j \in (-\pi/3, \pi/3)/\lambda\).

To optimize the spring parameters, we apply the method introduced in Sec. 3.2, with optimization constraints

\[
\begin{align*}
k_1 > 0, & \quad k_2 > 0, & \quad k_3 > 0, \\
\frac{\pi}{2} < \delta_1 < \frac{\pi}{2}. &
\end{align*}
\]

4.2 Results. All the simulations are computed for a manipulator with base side \(1\)m and platform side \(0.75\)m. The offsets of the base and platform attachments correspond to \(\lambda = 0.1\)m in Eq. (25).

We discretize the workspace in position and orientations as follows. Consider the vector \(\mathbf{A}\) orthogonal to the platform plane. We define the rotations of the platform as the cone of possible directions of the vector \(\mathbf{A}\) that spans two dimensions of possible rotations \((R_1\) and \(R_2\)), where the maximum angle between two possible \(\mathbf{A}\) vectors represents the opening angle of the cone [33]. The additional rotation around \(\mathbf{A}\) represents the 3rd dimension of rotations \((R_3\) Fig. 4). We consider a discretization of the 6-dim workspace of 13,247 configurations that include a range of directions of \(\mathbf{A}\) inside of a cone with opening angle of \(5\pi/6\) rad and \(R_2\) from \(-\pi/3\) to \(\pi/3\). The prismatic joint limits are \(l_i \in [0.5, 1]\), and the universal joint limits are \(\theta_j \in (-\pi/3, \pi/3)/\lambda\).

To optimize the spring parameters, we apply the method introduced in Sec. 3.2, with optimization constraints

\[
\begin{align*}
k_1 > 0, & \quad k_2 > 0, & \quad k_3 > 0, \\
\frac{\pi}{2} < \delta_1 < \frac{\pi}{2}. &
\end{align*}
\]
For the optimization, we only consider configurations where the platform position vectors are inside the sphere shown in Fig. 4-left and the orientation inside the cone in Fig. 4-right. We denote the interior of the sphere and the orientations inside the cone as the central workspace, and focus efforts on the reduction of motor force in these workspace regions. With a single applied force of \( W = (0, 0, -10, 0, 0, 0) \), the obtained optimum is

\[
\begin{align*}
    k_1 &= 0.52, & k_2 &= 1.31, & k_3 &= 1.68, \\
    \delta_1 &= -0.92, & \delta_2 &= -0.03, & l_0 &= 1.5
\end{align*}
\]  

(30)

Considering a collection of applied forces on the border of a cone with opening angle of \( \frac{2\pi}{3} \) rad (shown as black arrows in Fig. 6), all of magnitude 10, the optimization gives

\[
\begin{align*}
    k_1 &= 0.290, & k_2 &= 0.725, & k_3 &= 0.93, \\
    \delta_1 &= -0.916, & \delta_2 &= -0.03, & l_0 &= 1.5
\end{align*}
\]

(31)

In Fig. 5(a), we show the computation of the overall reduction of the actuation torque using the compliant parameters in Eq. (31). The net percentage of increase of the overall torque, computed using Eq. (19) for an applied force \( W = (0, 0, -10, 0, 0, 0) \) is \(-84.08\%\). Figure 5(a) top shows the histogram of the percentages of increase in all configurations of the WS. At the bottom, each position dot is plotted with a color according to the mean value of percentage of increase for all the achievable orientations from the position. Note that all the configurations of the workspace experience a reduction for this applied force.

If we assume that the motors can exert half of the force applied at the platform (that is, 5 N for an expected load of 10 N), the static workspace is defined by those configurations that do not reach that limit. Without compliance, the static workspace is 71.9\% of the kinematic workspace. Using compliance, it is 91.7\% of the kinematic workspace. Figure 5(b) shows the distribution of the maximum torque over the workspace with and without compliance, and a representation of the position static workspace.
Figures 6 and 7 show how the increase of actuation force changes when different external forces are applied. Net increases and decreases are computed with respect to the central workspace, that is, the amount of workspace inside the sphere and cone of orientations shown in Fig. 4. In Fig. 6-top, we show a manipulator using the spring parameters in Eq. (31). Each arrow represents a direction of applied external force with magnitude 10 N. The number next to the arrow represents the net percentage of increase of the maximum exerted torque over the central workspace, computed using Eq. (22). The colors follow the color code of the second bar (reds/oranges for positive increases, and yellows/blues for negative increases, i.e., decreases). In the spheres in Fig. 7-bottom, we only plot the tip dot of the arrows, and thus, each dot corresponds to an applied force with direction going from the center to the sphere to the dot, with magnitude 10 N. In the first column of Fig. 7-bottom, each color represents the percentage of workspace where there is a reduction of the overall motor force (first row) or the maximum exerted motor force (second row). In the second column the colors represent the total percentage of increase of the overall torque using Eq. (19) (first row) and the percentage of increase of the maximum exerted motor force using Eq. (23) (second row). With this sphere representation, we can see what range of forces results in a net reduction of motor force.

In Fig. 7, the top plot shows percentages of workspace where there is a decrease of the overall torque when the magnitude of the force changes. The middle plot shows the mean decrease in the central workspace. In all the plots, the x-axis represents the magnitude of the applied force, which direction is identified depending on the color, following the chart in the figure. Solid lines correspond to a manipulator optimized for a range of forces (parameters in Eq. (31)) while dashed lines are results for a manipulator optimized for a single force (parameters in Eq. (30)). The first manipulator gets bigger portions of workspace with reduction when the resultant applied force is not vertical.

5 Example Application II: The 3-URS Platform

Consider the manipulator in Fig. 8-top. It is a 6 DOF manipulator with 3 equal legs consisting of 2 links and 3 rotational joints each. For each leg $l$, $z_l = (0, 0, 1)^T$ is the axis of rotation of the first joint, with rotation angle $\theta_{l1}$. The axis of rotation of the second joint is $z_2 = (\sin(\theta_{l1}), -\cos(\theta_{l1}), 0)^T$ with a rotation angle $\theta_{l2}$. Finally, the third axis is parallel to the previous one, with angle of rotation $\theta_{l3}$.

5.1 Kinematic Analysis and Jacobian Matrix. As in the previous example, the coordinates of the attachments, with respect to the fixed reference frame located at the center of the base, are $p_i = P_i$ and

$$q_i = p_i + RQ_i, \quad i = 1, 2, 3$$

(32)

Alternatively, the coordinates of the platform attachments can also be parameterized with respect to the angles of rotation of the joint angles as

$$q_i = p_i + s_i(0, 0, 1)^T + r_i(\cos(\theta_{l1}), \sin(\theta_{l1}), 0)^T$$

(33)

where

$$s_i = l_i \sin(\theta_{l2}) + d_i \sin(\theta_{l2} + \theta_{l3}),$$

$$r_i = l_i \cos(\theta_{l2}) + d_i \cos(\theta_{l2} + \theta_{l3})$$

(34)

and $l_i$ and $d_i$ are the lengths of the links of the $i$th leg. We can obtain similar parameterization of the center points of the joints $\theta_{l3}$ [24].

The loop equations are the 9 equations obtained by equating the platform attachment coordinates computed with respect to the position and orientation of the platform $q_i'$ (Eq. (32)) with the same coordinates computed using the joint angles $q_i'$ (Eq. (33)).

The manipulator has 3 legs with 2 links each, and a total of 6 joints per leg (2 in the base universal joint, 1 in the rotational joint and 3 in the platform attachment spherical joint). The mobility of the platform is 6 (full mobility) and therefore, only 6 motors are needed to fully actuate the platform in all its degrees of freedom. We consider all joints compliant except the platform attachments, with only two motors per leg, located at the two base joints.

The Jacobian matrix $J^i_{6k}$ can be computed using screw theory following the steps proposed Sec. 2.2. In this case, the Jacobian matrices are

$$J^{-1}_{6k} = 
\begin{bmatrix}
-1 & 0 & 0 \\
\frac{1}{l_i} \cos(\theta_{l2}) + d_i \sin(\theta_{l2} + \theta_{l3}) & 0 & 0 \\
0 & \frac{1}{l_i d_i \sin(\theta_{l3})} & 0 \\
0 & 0 & \frac{-1}{l_i d_i \sin(\theta_{l3})}
\end{bmatrix}$$
and $J_T = (\xi_{ij})^T$ is a matrix where each row $\xi_{ij}$ is defined as

$$
\xi_{i1} = (\xi_{i2}, \quad q_i \times z_2)^T
$$

$$
\xi_{i2} = (q_i - t_i, \quad q_i \times (q_i - t_i))^T
$$

$$
\xi_{i3} = (q_i - p_i, \quad q_i \times (q_i - p_i))^T
$$

for $i = 1, 2, 3$, where the vector $z_2 = (\sin(\theta_3), -\cos(\theta_1), 0)^T$ has been introduced before as the second joint axis of rotation and $t_i$ are the center points of the third joints at each leg $i$.

Note that the Jacobian matrix $J = J_T^T J_T$ is a $9 \times 6$ matrix and the static equilibrium equation in Eq. (14) has a vector of compliant torques

$$
\tau_e = \begin{bmatrix}
\vdots \\
k_1(\theta_1 - \delta_1) \\
k_2(\theta_2 - \delta_2) \\
k_3(\theta_3 - \delta_3) \\
\vdots
\end{bmatrix}
$$

(35)

for $i = 1, 2, 3$, where $k_i$ are the 3 spring constants and $\delta_1$, $\delta_2$, and $\delta_3$ the five parameters for the spring free lengths. We omit the sub-index $i$ for the spring parameters that are equal for each leg.

The vector of motor torques contain only 6 nonzero elements, because $\tau_{1i} = 0$ for $i = 1, 2, 3$. Then, the static equilibrium system becomes square as in Eq. (15).

5.2 Results. For the simulations, we considered a manipulator with dimensions $a = 0.7$, $b = 0.2$, $l_i = 1/3$, and $d_i = 2/3$, for $i = 1, 2, 3$. Using the same discretization of the workspace as in the previous example, we solve the inverse kinematics in each configuration to get the corresponding angle joints. The spherical attachments are considered with a range of motion forming a cone with opening angle of 140 deg.

For the results in all the tables, we discard the configurations too close to a singularity, that is, where the determinant of the Jacobian matrix is smaller than $10^{-5}$.

Following similar steps to the previous example, we apply the optimization of the range of forces shown in black in Fig. 12 for forces of magnitude 10 N. The results give

$$
k_1 = 0.94, \quad k_2 = 0.45, \quad k_3 = 0.54
$$

$$
\delta_{11} = 0, \quad \delta_{12} = \frac{2\pi}{3}, \quad \delta_{13} = \frac{4\pi}{3}, \quad \delta_{2} = 0, \quad \delta_{3} = 0
$$

(36)

If we instead perform the same optimization for forces of magnitude 2 N (in the same directions), then the optimal parameters obtained are the same as before, except the spring constants are divided by 5 (proportional to the applied forces).
Optimizing for a single force \((0,0,-10,0,0)\) gives

\[
\begin{align*}
    k_1 &= 1.69, \quad k_2 = 0.80, \quad k_3 = 0.98, \\
    \delta_{11} &= 0, \quad \delta_{12} = \frac{2\pi}{3}, \quad \delta_{13} = \frac{4\pi}{3}, \\
    \delta_2 &= 0, \quad \delta_3 = 0
\end{align*}
\]

Equation (37)

Figure 9 shows the distribution of configurations for which there is reduction of overall torque when a force \(F = (0,0,-10,0,0)\) is applied, using Eq. (18). The color of each dot in the workspace represents the mean value of Eq. (18) for the configurations corresponding to all the possible orientations from the dot position. As a global measurement, using the spring parameters in Eq. (36), 88.4% of the configurations in the workspace represent the mean value of Eq. (18) for the configurations corresponding to all the possible orientations from the dot position. The net reduction over all the workspace, computed as in Eq. (19), is −58.25%.

Figure 10 shows the modification of the static workspace. In this case, we set the limit of the motor torques to 10 Nm. When applying the vertical force \((0,0,-10,0,0)\), the manipulator without springs can reach only 26.77% of the kinematic workspace. With the springs, the reachable workspace increases to 47.67% of the kinematic workspace. Figure 10 shows a representation of the position static workspace and the histogram of the maximum motor torque in all the configurations of the workspace for a manipulator without springs (dark color/red) and the manipulator using the springs with parameters in Eq. (36) (light color/yellow).

Figures 11 and 12 show results where different applied forces are considered, showing reductions/increases of the motor torque for the central regions of the WS similarly as in the previous example. Figure 11 shows how results change when the magnitude of the applied force changes. Dashed lines show results for the optimum obtained with a range of applied forces of magnitude 2 N, and solid lines optimums obtained with 10 N range of applied forces. Different colors correspond to different directions of the applied forces shown in the diagram.

Finally, Fig. 12 shows the reduction over the central workspace for all the possible applied force directions, for a manipulator using the parameters in Eq. (36). The net increases in all the WS are computed using Eq. (19) for the overall motor torque and Eq. (23) for the maximum motor torque.

### 6 Discussion

The results for the two parallel manipulators analyzed show that for a desired range of force directions applied on the platform, springs can help to significantly reduce the motor torque.

Figures 6 and 12 show that springs cannot reduce the motor torque for all possible applied forces, because if there is reduction of actuation force under one force direction, there will be increase in the opposite one. However, we have provided design tools to optimize the manipulator for the desired range of external forces, and the desired regions of the workspace where motor force reduction occurs. This allows users to specify the desired workspace regions and directions of forces for which the most significant motor torque reduction is needed.

If a manipulator has to perform tasks with a preferred direction of external applied forces, as for example a flight simulator, the static workspace, which defines the real borders of the reachable workspace, can be greatly increased by an appropriate selection of the springs. For a more versatile and general-use manipulator, springs in parallel with the motors may not be a good design solution.

The curves in Figs. 7 and 11 indicate that the performance under lower forces can significantly increase the motor torques instead of reducing it, but a significant reduction will occur for larger forces. Therefore, we can conclude that the springs have to be designed to compensate the minimum external force the manipulator has to resist, for instance, the weight of the platform.
Other approaches to reduce actuation torque on parallel manipulators like static balance or gravity compensation methods require a complex design and an ad-hoc location of the compliant elements. However, we have shown that by simply locating springs in parallel with the motors, large reductions of actuation torque can be also obtained.

This simple solution to reduce actuation torque has been applied in industry for simple cases, as for instance, using springs in parallel with the prismatic motors of industrial electric jacks. Here, we provide a method to implement similar reductions for more complex architectures including active and passive (rotational and prismatic) joints.

7 Conclusions

We have presented a mathematical framework that clearly distinguishes between active and passive compliant joints. The framework can be used to model compliant parallel manipulators by changing the definition of the compliant actuated joint torque, with the spring serially connected to the motor as in Ref. [6]. In this case, the proposed formulation show simpler static equilibrium equations than previous approaches, as it only requires the computation of one Jacobian matrix instead of the Jacobian between passive and active joints.

The quantification of the variation of the torques due to the presence of passive compliance has been expressed in an analytical equation that allows us to study such variation through all the workspace of the manipulator.

The framework has been successfully applied to two examples of manipulators that show a significant reduction of the actuator forces for a significant range of forces and portions of the workspace.

In a future work, we want to study the influence of compliance when it acts in parallel with a pulling cable in underactuated hands manipulating objects [3]. In one torque direction, the compliance acts in parallel and thus, it behaves as in the proposed model, but in the other direction the cable becomes loose and the compliant joints become passively compliant.

The presented analysis, together with the existing compliant parallel robots analysis, constitutes a further step toward a full understanding of the role of compliant joints in parallel manipulators.
